TECHNICAL NOTE NO. 1226

THEORETICAL SUPERSONIC LIFT AND DRAG CHARACTEREFTICS

OF SYMMETRICAL WEDGE-SHAPE-AIRFOIL SECTIONS AS

AFFECTED BY SWEEPBACK OUTSIDE THE MACH CONE

By H. Reese Ivey and Edward M. Bowen, Jr.

SUMMARY

The theoretical supersonic section lift and drag characteristics of thin, wedge-shape, untapered airfoils with sweepback are presented. The results apply to those parts of the wing in two-dimensional flow and are not applicable to wings swept back within the Mach cone of the center section. The results may also be applied to swept-forward wings if the angle of sweep is not enough to put the wing within the Mach cone from the tips.

INTRODUCTION

A simplified method is presented in reference 1 for determining the pressure distribution around thin, sharp-nose airfoils at supersonic speeds. This method considers the entropy increase through the shock waves and calculates the pressure changes through the shock and expansion waves. The method was shown to be accurate for wedge-shape airfoils and to give a close approximation for continuously curving airfoils. The calculated pressure distribution was shown to check the experimental distribution at law Roynolds numbers except for a small region of esparated flow near the trailing edge. The type of flow encountered when extreme sweepback (within the Mach come) is used at supersonic speeds is discussed in reference 4. In that report it was shown that low drug coefficients could be obtained when the wing was compt back sufficiently to make the velocity component perpendicular to the leading edge of the wing subsonic. Experimental results at higher Reynolds numbers show that the region of breakayay becomes negligible as the keynolds number increases and hence the calculations should be accurate for full-scale sircraft.

Reference 2 used the method of reference 1 to calculate the characteristics of thin double-wedge airfoils at supersonic speeds.

The section characteristics for wing sections swept back outside the Mach come were first determined by Busemann in reference 3. In that paper the component theory was introduced and used to calculate some of the airful characteristics of swept-back wings.

The present paper extends the work of Bucemann (reference 3) and makes use of the component theory in conjunction with the method of reference 1 to determine the section lift and drag characteristics of nwept-back double-wedge-airfoil sections. A brief discussion is included of the trends indicated by the results.

THEORETICAL CONSIDERATIONS

The equations of Meyer as given in reference 5 show that the velocity components normal to any plane shock (herein designated u_b , before shock, and u_a , after shock) are related to the speed of sound before the shock corresponding to a Mach number of unity and the free-stream-velocity component in the plane of the shock by the following equation:

$$u_b u_a = (a_{M-1})^2 - \frac{\gamma - 1}{\gamma + 1} v^2$$

Man Carry Halance

where

speed of sound corresponding to a Mach number of unity before shock $\left(\binom{a_{M=0}}{7+1}\right)$

component of free-stream velocity in plane of shock

stagnation speed of sound before shock

Since

$$(a_{M=0})^2 = a_b^2 \left(1 + \frac{\gamma - 1}{2} M_b^2\right)$$

and

$$a_b^2 M_0^2 = u_b^2 + v^2$$

it follows that

$$u_b u_a = \frac{2a_b^2}{7+1} + \frac{7-1}{7+1} u_b^2$$

From this relation it can be seen that, for a given value of local speed of sound before the shock $a_{\rm b}$, the change of stato across a plane shock is determined only by the free-stream-velocity component normal to the shock riene $a_{\rm b}$. This fact is useful in calculating the theoretical section pressure distributions of the swept-back wings considered herein.

The obvious limitations to the method are that the wing section considered must not be swept pack within the Mach cone of the center section and that the wing section should not exceed the limits illustrated in figures 3 and 4 of reference 1.

For the present study the free-stream-velocity vector is broken into components, one of which is parallel to the leading edge of the wing and is therefore in the plane of the attached shock wave. Since this component of free-stream velocity has been shown to have no effect on the change of state across the shock, the pressure distributions can be calculated from the velocity vectors normal to the leading edge.

For wings swept back outside the Mach cone a part of the wing is, effectively, in two-dimensional flow. Figure 1 defines the zones of two-dimensional flow for the wing plan forms considered in the precent paper. The part of the wing lying in the central and tip areas indicated in figure 1 will have considerable threedimensional flow. The calculations presented are valid only for the part of the wing in two-dimensional flow. The characteristics of a swept-back wing of finite aspect ratio (tips and center section being considered) can be approximated by a combination of the results presented herein and the linearized method of reference 6. The calculations presented herein are suitable for swept-forward as well as swept-back wings. In order to illustrate the effect of sweepback on lift and drag, a simplified analysis of the flow over the example wing shown in figure 2 will be discussed first. For this example, the wing is assumed to be operating under the following conditions:

Free-streem Mac'ı numbor, Mo	Ħ
Angle of attack, ao, de rees	
Thickness ratio perpendicular to the leading edge, $\begin{pmatrix} t \\ c \end{pmatrix}_e$ 0.	.03
Sweenback angle, A. degrees	60

Figure 2 gives plane and side elevation views of the example wing for the operating conditions specified. Figure 2 differentiates between two methods of measuring section thickness ratio; namely, perpendicular to leading edge (section A-A) or parallel to free-stream direction (rection B-B). In general, all calculations are carried out for values of $\begin{pmatrix} t \\ c \end{pmatrix}_0 = 0.05$ and $\begin{pmatrix} k \\ c \end{pmatrix}_0 = 0.05$ and 0.10.

The subscript "e" signifies effective and indicater that the component is measured perpendicular to the leading edge and the subscript "o", that the component is measured in the direction of the free-stream velocity. In order to make the ecleulations the free-stream kach number vector is broken into three components: M₁ perpendicular to the leading edge and lying in the plane determined by the chord lines, M₂ perpendicular to the plane determined by the chord lines, and M₃ parallel to the leading

edge. Except for tip effects, which do not influence the section being studied, the flew parallel to the leading cdge does not affect the pressure distribution and honce will be neglected.

In order to expedite the calculations for the illustrative example, some simplified equations are used instead of the exact equations which are given in the appendix. It must be emphasized that the approximate method has been used only in the illustrative example.

For small engles of attack

MI = Mo cos A = 2

and

Now an effective angle of attack α_0 is based on M_1 and M_2 instead of M_0 . The vector sum of M_1 and M_2 is effective free-stream Mach number M_0 . The offective angle of attack α_0 is then

$$\alpha_{\rm e} = {\rm arc} \ {\rm tan} \ \frac{M_2}{M_1} \approx {\rm arc} \ {\rm tan} \ M_3 \ {\rm sin} \ \frac{\alpha_0}{M_0} \cos \Lambda$$

For small angles of attack, sin α_0 and tan α_0 may be replaced. by α_0 . Then

$$\alpha_0 = \arctan \frac{\alpha_0}{\cos A} \approx 2^0$$

and since $M_0 = \sqrt{M_1^2 + M_2^2} \approx M_1$, the problem has been simplified to the extent that the lift and drng characteristics of an unswept wing section at 2° angle of attack and Mach number 2 can be used. Reference 2 gives the pressure drag coefficient of this airfoil as

$$c_d = 0.0085$$

and the lift coefficient as

c₂ = 0.082

These coefficients are based on the dynamic pressure corresponding to Ma. In order to bass them on Mo the coefficients must be = cos2A . It must slee be remembered that only multiplied by one component, $c_{\tilde{d}} \cos A$, of the drag force is in the free-stream direction; consequently, the lift and pressure-drag coefficients based on free-stream conditions become

$$c_{1_0} = 0.082 \times 0.5^2 = 0.0205$$

 $c_{d_0} = 0.0085 \times 0.5^3 = 0.00106$

Some allowance must be made for skin friction, which is changed only by a Raynolds number effect due to the sweepback. The exact nature of supersonic skin-friction drag is not as yet completely defined but for the present analysis its effect can be shown by assuming that the supersonic exin-drag coefficient remains conetant in the supersonic range at a reasonable subsonic value. If the effect of a skin-friction coefficient other than the value assumed herein is desired, the curves presented in this paper may be ehifted accordingly. For this example the skin-friction drag coefficient is assumed to be 0.006 and the total drag coefficient is

The pressure drag is thus only a small part of the total drag. Reference 2 may be used to determine the section lift and drag ocefficients of an unswept wing with a thickness ratio of 5 percent when thickness is measured perpendicular to leading edge for $\alpha_0 = 10$ and Mo = 4. These data may be compared with the swept-back-wing section coefficiente, as followe:

> Swept-back Unswept wing wing, $\Lambda = 60^{\circ}$ 0.00706 0.00900 0.0180

In this particular case the addition of sweepback increased the lift and decreased the drag of the section. It must be remembered, however, that this example serves only to point out the problems involved in calculating the airfoll characteristics of swept-back wings and is not intended to lead to any particular conclusions as to the general advantage of sweepback. Some of the equations used for this illustrative example are approximations which do not apply at high angles of attack. The exact equations used in order that the main body of the paper not be unnecessarily complicated.

PRESENTATION OF RESULTS

Slope of the lift curve. - Reference 2 has shown that the slope of the lift curve decreases as the Mach number increases above 1.0. It can be expected, therefore, that the addition of sweepback at high supersonic speeds with tend to increase the lift by making the effective Mach number approach 1 and by increasing the effective angle of attack but will tend to decrease the lift by decreasing the effective dynamic pressure. The resultant effect depends in the actual speeds and angles involved.

Figure 3 presents the variation with the sweepback of the slope of the section lift curves (based on free-stream angles of attack and free-stream lift coefficients) for a wing section of 5-percent effective thickness ratio. Curves are given for constant values of free-stream Mach number. The curves show that at low supersonic speeds substantial increases in the slope of the lift curve are the result of increasing angle of sweepback. For

example, at $M_0 = 1.5$, $\frac{dc_{1_0}}{da_0} = 0.0630$ for $\Lambda = 0^{\circ}$ and dc_{1_0}/da_0

has increased to a value of 0.0735 for $\Lambda=30^{\circ}$. However, at higher forward Mach numbers the elepe of the lift curve does not change appreciably with increasing exceptack until the sweepback is sufficient to reduce the effective Mach number to the vicinity of unity.

Since reference 2 has shown that thickness ratio has no appreciable effect on the slepe of the lift curve, figure 3 has been limited to a single value of thickness ratio.

Minimum drag coefficient. The effect of sweephack on the section minimum drag coefficients is shown in figure 4.

If the thickness ratio measured in the free-stream direction is held constent, the section minimum drag coefficient will in general increase slightly with an increase in sweepback. If the effective thickness ratio is held constant, the drag coefficient may decrease sporeciably before increasing. This decrease is evident at Much numbers considerably greater than unity. (See

Ratio of soction lift to diag. The ratio of section lift to section drag has been acleuted as the ranameter which represents most clearly the effectiveness of an airfoil section acting as a lifting device. This parameter has been calculated and plotted as a function of section lift coefficient c; for various combinations of A, $\frac{L}{C}$, and M_O. (See table I.) The results include both the pressure drag and total drag. It should be noted that, wherever a combination of A, Clo, and Mc resulted in a value of offective Mach number Me less then the minimum value for which application of the method of reference 1 is considered valid, the curves were either emitted or restricted in extent. For operating conditions approaching these limits and with a wing of finite aspect ratic, the portion of the wing for which these calculatione are valid is a small percentage of the total wing area.

An examination of figures 5 through 16 yields the following general trends:

- (1) For a given combination of M_0 and $\left(\frac{t}{c}\right)$ an increase in the sweepback angle substantially increases the values of maximum clo and $\hat{c_d}_o$
- (2) For a given combination of M_0 and $\left(\frac{t}{c}\right)_0$ an increase in the sweepback angle does not appreciably affect the value of maximum or cdo + C.006
- (3) For a given combination of M_0 and $\left(\frac{t}{c}\right)$ or $\left(\frac{t}{c}\right)$ an increase in the sweepback angle has no appreciable effect on the increase in the sweethern $\frac{c_{i_0}}{c_{d_0}}$ or

(4) For a given combination of Λ and $\left(\frac{t}{c}\right)_e$ or $\left(\frac{t}{c}\right)_o$ and increase in the operating free-stream Mach number substantially decreases the value of c_{1_O} for maximum $\frac{c_{1_O}}{c_{d_O}}$ or $\frac{c_{1_O}}{c_{d_O}+0.006}$.

(5) For a given combination of Λ and $\left(\frac{t}{c}\right)_0$ or $\left(\frac{t}{c}\right)_0$ an increase in the operating free-stream Mach number decreases the value of maximum $\frac{c_{l_0}}{c_{d_0}+0.006}$ but has no appreciable effect on the value of maximum $\frac{c_{l_0}}{c_{d_0}}$.

It may be of interest to compare the evact results of the present paper with the approximate formulas developed from the linearized supersonic theory. The linearized theory is, of course, restricted to thin airfoils at small angles of attack and at stream

By use of the component theory the approximate formulae for determining the characteristics of the ratio of maximum lift to pressure drag of swept-back sections are

Mach numbers large enough to give an attached shock.

$$\left(\frac{L}{D}\right)_{\text{max}} = \frac{1}{2 \text{ cos } \Lambda} \left(\frac{c}{t}\right)_{\theta}$$

$$\alpha_{0} = \left(\frac{t}{c}\right)_{\theta} \text{ cos } \Lambda$$

$$C_{1_{0}} = \frac{4\left(\frac{t}{c}\right)_{\theta} \text{ cos}^{2} \Lambda}{\sqrt{\left(N_{1} \text{ cos } \Lambda\right)^{\frac{2}{s}} - 1}}$$

These formulas provide close approximation to the exact values of the present paper within the limits of their application.

It is evident that for both swept-back and unswept wedge-shape sections the maximum ratio of lift to pressure drag occurs when two eides of the wing section are parallel to the direction of flight.

CONCLUSTORS

The calculated results presented in this paper indicate that:

- 1. Increasing sweepback at a constant stream Mach number increases the value of the ratio of lift to pressure drag and the ratio of lift to total drag, provided that the thickness ratio measured in the free-stream direction is allowed to decrease.
- 2. Increasing sweepback at a constant stream Mach increases the slope of the lift curve substantially except at high stream Mach numbers where the effect is negligible.
- 3. Increasing sweepback at a constant stream Mach number decreases the minimum drag coefficient provided the free-stream thickness ratio is allowed to decrease.
- 4. The section lift coefficient for the maximum ratio of lift to pressure drag and of lift to total drag decreases with an increase in free-streen Mach number regardless of sweepback.
- 5. The approximate linearized solution for the lift and drag characteristics of a swept-back wing section at the maximum value of the ratio of lift to prossure drag agree well with the exact values of the present paper provided that: (a) the surfeil is thin, (b) the airful is at a small angle of attack, and (c) the free-atream Mach number is well above the minimum value for an attached shock.

APPENDIX

METEOD OF COMPUTATION

The following formulas are derived by the application of trigonemetry and analytic geometry to the basic wing sections considered. (See fig. 2.)

The effective Mach number M_{\odot} which is the component of the free-stream Mach number M_{\odot} acting perpendicular to the leading edge, is expressed in terms of the angle of sweepback Λ and the free-stream angle of attack α_{\odot} as

$$M_{\Theta} = M_{O} \sqrt{1 - \sin^2 \Lambda \cos^2 \alpha_{O}}$$

where

Me effective Mach number; that is, the component of Mo acting perpendicular to the leading edge

The effective Mach number Mo can be further broken up into

- (a) The component of $\rm\,M_{\odot}$ (and therefore also of $\rm\,M_{\odot})$ lying in the plane of the chord lines and perpendicular to the leading edge given by $\rm\,M_{\odot}$ cos α_{\odot} cos
- (b) The component of $\rm\,M_{\odot}$ (and therefore also of $\rm\,M_{\odot})$ perpendicular to the plane of the chord lines, given by $\rm\,M_{\odot}$ ein α_{\odot}

The effective angle of attack, that is, the engle of attack of the airfeil section measured perpendicular to the leading edge, is

$$\alpha_e = \arctan \frac{\tan \alpha_0}{\cos \Lambda}$$

and the effective thickness ratio, that is, the thickness ratio measured perpendicular to the leading edge, is

$$\left(\frac{\mathbf{t}}{\mathbf{c}}\right) = \frac{\left(\frac{\mathbf{t}}{\mathbf{c}}\right)_{1}}{\cos \Lambda}$$

If $\oint_{\mathbf{c}}$ is the half-angle of the airfoil measured perpendicular to the loading edge and $\beta_{\mathbf{c}}$ is the angle through which the flow turns (that is, change in surface angle of airfoil) measured in the plane perpendicular to leading edge, then

$$\phi_6 = \alpha_0 + \beta_0 = \arctan \frac{\left(\frac{t}{C}\right)_0}{\cos A}$$

Pressure coefficients $\frac{\Delta p}{q_0}$ are now determined by the method

of reference 1 for the effective airfoil section operating at the effective angle of attack and at the effective Mach number. These pressure coefficients are then converted to lift and drag section coefficients based on free-stream measurements by the following formulas:

$$c_{\mathbf{d}_{O}} = \frac{1}{2} \left(\frac{M_{o}}{M_{o}} \right)^{2} \left\{ \left[\frac{\Delta \mathbf{p}_{1}}{\mathbf{q}_{o}} - \frac{\Delta \mathbf{p}_{1}}{\mathbf{q}_{o}} \right] \left[\left(\frac{\mathbf{t}}{\mathbf{v}} \right)_{o} \cos \alpha_{o} - \sin \alpha_{o} \right] \right.$$

$$+ \left[-\frac{\Delta \mathbf{p}_{1}}{\mathbf{q}_{o}} + \frac{\Delta \mathbf{p}_{1}}{\mathbf{q}_{o}} \right] \left[\left(\frac{\mathbf{t}}{\mathbf{v}} \right)_{o} \cos \alpha_{o} + \sin \alpha_{o} \right]$$

$$= \frac{1}{2} \left(\frac{M_{o}}{\mathbf{v}} \right)^{2} \left[-\frac{\Delta \mathbf{p}_{1}}{\mathbf{q}_{o}} - \frac{\Delta \mathbf{p}_{1}}{\mathbf{v}} \right] \left[\left(\frac{\mathbf{t}}{\mathbf{v}} \right)_{o} \cos \alpha_{o} + \sin \alpha_{o} \right]$$

$$c_{l_0} = \frac{1}{2} \left(\frac{M_e}{M_o} \right)^2 \left\{ \left[-\frac{\Delta p_1}{q_o} + \frac{\Delta p_h}{q_o} \right] \left[\left(\frac{t}{c} \right)_o \sin \alpha_o + \cos \alpha_o \right] \right.$$

$$+ \left[-\frac{\Delta p_2}{q_o} + \frac{\Delta p_3}{q_o} \right] \left[-\left(\frac{t}{c} \right)_o \sin \alpha_o + \cos \alpha_o \right]$$

where the subscripts 1 and 2 refer to the leading and trailing parts, respectively, of the upper surface of the airfeil and the subscripts 3 and 4 refer to the leading and trailing parts, respectively, of the lower surface.

SECTION: Wings and Airfoils (6) CROSS REFERENCES: Wings - Aerodomanics (99150): TN-1226 Pressure distribution - Wings **REVISIO** AUTHOR(S) (74500) AMER. TITLE: Theoretical supersonic lift and drag characteristics of symmetrical wedge-sha airfoil sections as affected by sweepback outside the Mach cone. FORG'N TITLE. DRIGINATING AGENCY: National Advisory Committee for Aeronautics, Washington, D. C. TRANSLATION. COUNTRY LANGUAGE FORG'N.CLASS U. S.CLASS. | DATE PAGES ILLUS. FEATURES U.S. Eng. Unclass. Mar'47 60 45 tables, diagrs, graphs ARSTRACT Report extends work of Busemann using component theory and simplified method for determining pressure distribution around thin, sharp-nosed airfoils at superaonic speeds Results indicate that increasing sweepback at constant-stream Mach increases lift/ pressure drag and lift/total drag ratios, provided thickness ratio decreases, increases slope of lift curve, and decreases minimum drag coefficient. Section lift coefficient for maximum lift/pressure drag and lift/total drag ratios decreases with increase in free stream Mach.
